Mechanical behavior of a Ti-6Al-4 V titanium alloy with microstructural evolution modeling under hot and superplastic conditions

Mechanisches Verhalten einer Ti-6Al-4 V-Titanlegierung mit mikrostruktureller Evolutionsmodellierung unter warmen und superplastischen Bedingungen.

M. W. dos Santos¹, V. Velay², V. Vidal², G. Bernhart², G. F. Batalha¹, H. Matsumoto³

The present work aims at evaluating and understanding the mechanical behavior of a Ti-6Al-4 V alloy under hot and superplastic forming conditions. Tensile tests were performed at temperature range from 650 °C to 950 °C, at strain rates between \(10^{-2}\) s\(^{-1}\) and \(10^{-4}\) s\(^{-1}\). Three equiaxed microstructures, each characterized by a different starting grain size (4.9 µm, 3.0 µm and 0.5 µm), are compared to better understand the microstructural evolutions under hot and superplastic forming conditions and their influence on the mechanical behavior. Hence, an accurate model with microstructural considerations is proposed. The model capabilities consider the grain size evolution that is influenced by the temperature and deformation. The computed flow stresses strongly depend on the strain rate and on the considered initial grain size. Temperature and strain rate conditions may lead to a strain hardening phenomenon in some cases. The comparison between the model response and experiment shows a good agreement for all the tests carried out on Ti-6Al-4 V.

### 1 Introduction

During hot and superplastic forming processes, the sheet forming capabilities depend on the selected alloy (microstructural properties and chemical composition) and on the process parameters (temperature and strain rate). The Ti-6Al-4 V alloy is a typical α + β titanium alloy, wherein the element aluminum acts as an α phase (HC) stabilizer and the element vanadium acts as a β phase (BCC) stabilizer [1]. The attractive properties such as high strength to weight ratio, good fatigue properties and excellent corrosion resistance, have made Ti-6Al-4 V a leading option for manufacturing aerospace and biomedical components.

The development of the superplastic forming technology significantly contributes to manufacturing titanium alloy products of high performance with low cost and short cycle. In the hot forming process of titanium alloys, temperature control is essential due to the phase transformations that may cause degradation of the mechanical properties or even the embrittlement formed in the temperature range 940–980 °C [2].

In the present work, several tensile tests performed on flat specimens in Ti–6Al–4 V alloy at different temperatures and strain rates, were conducted by using a MTS hydraulic test machine. The thermo-mechanical behavior was analyzed under hot forming conditions with a temperature range from 700 °C to 950 °C and a strain rate (\( \dot{\varepsilon} \)) from \( 10^{-2} \) s\(^{-1} \) to \( 10^{3} \) s\(^{-1} \). In addition, a behavior model is formulated and the constitutive parameters were identified from the previous tests [3]. It allows the prediction of both microstructural evolutions and strain-stress curves under variant temperature and strain rate conditions. The comparison with experiment are in a good agreement.

**Bild 1.** Wahre Spannung gegenüber wahrer Dehnung. (a) Einfluss der Startmikrostruktur und (b) Einfluss der Testtemperatur.
2 Hot forming and microstructural evolution model

The mechanical behavior was investigated through the true stress versus true strain curves and considers three different equiaxed starting microstructure with initial average $\alpha$ grain sizes of 0.5 µm; 3.0 µm and 4.9 µm, Figure 1a, b. The grain growth of Ti–6Al–4 V alloy was quantified by using scanning electron microscopy (SEM) observations and image analysis. Hence, the relationships between the microstructural evolution, strain rates and temperatures were analyzed. The grain boundary sliding (GBS) and grain growth play an important role in flow stress and hardening [4]. From these observations, an optimization procedure was implemented for identifying the model parameters and studying the influence of the starting microstructure and its evolution on the mechanical properties of the Ti-6Al-4 V alloy. Regarding our test conditions, the grain growth effect of the $\alpha$-phase was assumed to be the major mechanisms affecting the mechanical properties. This phenomenon was taken into account by using evolution equations from literature [5-7].

3 Materials and experimental procedure

The typical chemical composition of the Ti-6Al-4 V titanium alloy investigated in the present work is referred to typical $\alpha + \beta$ titanium alloy, Table 1.

The mechanical tensile tests were performed by using a servo-hydraulic testing machine and a furnace suitable and accurate for the very large elongations. It includes three heating zones controlled by five thermocouples and allows maintaining a constant temperature all along the sample deformation.

4 Microstructural characterization

4.1 Procedure

Three different equiaxed α grain starting microstructures were compared and the mechanical tests (dynamic tests) performed at different temperatures, strain rates and starting microstructures, Table 2. In addition, several annealing tests (static tests) were added under the same time-temperature conditions to investigate...
the temperature and straining effects separately from each other. The eight levels of temperatures ranging from 700 °C to 920 °C and the five different strain rates ranging from $10^{-4} \text{s}^{-1}$ to $10^{-2} \text{s}^{-1}$ were considered.

For each test condition, a microstructural investigation was conducted using scanning electron microscopy observations. This allows comparing the starting microstructure and its evolution over time, temperature and deformation.

Three different microstructures were compared: the first one, designed as ultrafine-grained microstructure (UFGM), was obtained by using a combined "forging-rolling" process providing plates with thicknesses from 1.4 mm to 1 mm and an average grain size of 0.5 μm, Figure 2a [8]. A second and a third starting microstructure (SM), belongs to the most widely used starting microstructure (SM) for superplastic forming (SPF), Figure 2b, c. It considers an equiaxed ($\alpha + \beta$) Ti-6Al-4 V alloy with an average α phase grain size equal to 3 μm and 4.9 μm, respectively [9, 10].

As mentioned before, grain growth was investigated by conducting static and dynamic tests. The static tests were carried out at several temperatures and for different exposure times like those considered during the dynamic tests. A grain growth evolution was noted during the static tests done at the temperature 870 °C and the several exposure times 120 s, 2,100 s and 23,400 s, Figure 3.

A grain growth evolution was also observed for the case of the dynamic tests carried out at the temperature 870 °C under different strain rates: $\dot{\varepsilon} = 10^{-2} \text{s}^{-1}$, $\dot{\varepsilon} = 10^{-3} \text{s}^{-1}$ and $\dot{\varepsilon} = 10^{-4} \text{s}^{-1}$, Figure 4.
4.2 Grain growth predictions under static conditions

The grain growth will be defined as an internal variable of the behavior model. In this section, the grain growth evolution model is described in Equation 4 [4]. The identification procedure is based on both present experiments and results given by the Semiatin’s empirical law given in Equation 5, where the static coefficient \( K_s \) was determined at different temperature levels, allowing its interpolation with a more important temperature range [5, 6], Figure 5.

where \( A_1 \) and \( m_1 \) depend on temperature \( T \).

Computed grain growth-time and computed grain growth-strain curves were compared using the evolution law identified with the coarsening rate constants by Semiatin and coworkers and the experimental measurements performed under temperatures ranging from 700 °C to 920 °C and an initial grain size \( d_0 = 3 \) µm; as well as for the temperature of 800 °C and an initial grain size \( d_0 = 4.9 \) µm, Figure 8 [6].

\section*{5 Mechanical characterization}

\subsection*{5.1 Experiment}

The stress-strain response was investigated for 4.9 µm and 3.0 µm grain size microstructures and temperatures ranging from 800 °C to 870 °C. It illustrates a behavior with a significant strain rate sensitivity, Figure 9.

It was compared the strain-stress curves obtained at the temperatures 750 °C and 870 °C for two starting microstructures \((d_0 = 0.5 \) µm and \( d_0 = 4.9 \) µm). In each case, strain rates ranging from \( 10^{-4} \) s\(^{-1} \) to \( 10^{-2} \) s\(^{-1} \) are considered. The ultra-fine grain (UFG) microstructure eases a grain boundary sliding (GBS) mechanism. Therefore, it induces lower flow stresses and more important elongations compared to the starting microstructure of 4.9 µm. For some test conditions, (lower strain rates) a strain hardening effect is observed mainly due to grain growth. A slight stress increase occurs for the starting microstructure of 4.9 mm at 750 °C and 870 °C and for a strain rate of \( 10^{-2} \) s\(^{-1} \). However, it becomes more significant for the ultra-fine grain (UFG) microstructure corresponding to a more important grain growth, Figure 10.
5.2 Behavior modelling

This part deals with the constitutive equations able to reproduce the thermomechanical strain-stress response of Ti-6Al-4 V titanium alloy under hot and superplastic forming conditions. The behavior model is introduced in detail [10]. The constitutive equations represent the proposed approach and can consider, Table 3:

– the strain rate sensitivity
– the temperature effect
– variant starting microstructures and their evolutions over time, temperature and deformation
– when occurring, strain hardening effect eased for the ultra-fine grain (UFG) microstructure and low strain rates

The identification of the model parameters is described in detail where the model gives prediction in a good agreement with experiment for two starting microstructures [10]. In the present study, the model predictions are extended to the starting microstructure of 4.9 μm.

At 700 °C, it was not identified a deformation mechanism change for the initial grain size of \(d_0 = 4.9 \mu m\), whereas, this effect is observed and well assessed at lower strain rate (\(10^{-4} \text{s}^{-1}\)) for an initial grain size of \(d_0 = 0.5 \mu m\), Figure 11.

In the case of the starting microstructure of 0.5 μm, the behavior model predicts a stress decrease under certain conditions at \(10^{-2} \text{s}^{-1}\), Figure 12. This is due to a non-constant strain rate applied during the test, inducing a slight strain rate decrease with the sample elongation.

Whatever the test conditions and the starting microstructure considered, the model responses pro-
vide a good prediction of the whole experimental database.

6 Conclusions

The superplastic behavior of a Ti–6Al–4 V Titanium alloy was investigated under hot forming conditions regarding three different starting micro-structures with an average $\alpha$ grain size of 0.5, 3 and 4.9 μm. A temperature range from 700 °C to 920 °C and different strain rates between $10^{-4}$ s$^{-1}$ and $10^{-2}$ s$^{-1}$ were considered.

The parameters of a grain growth model are identified and the measurements performed successfully describe the predicted evolutions [6].

The internal variable related to grain growth was introduced into the mechanical model through the viscous flow and the hardening variable.

The following results can be drawn:
- the strain-stress response exhibits a viscous flow dependent on the test temperature, the initial microstructure and the grain growth
- a strain hardening is observed for the initial-period of the test due to the grain growth evolution.
- the viscous flow was dependent on the initial microstructure and its evolution
- the strain hardening was observed during the beginning of the test due to the grain growth evolution.

At the higher temperatures ($T > 900 ^\circ C$) the model formulation must be improved by adding a new mechanism related to the $\beta$ phase whose effect becomes predominant.
